

Foundational Framework for a Probabilistic Spacetime Ontology

Luciano Ciamarone

March 10, 2026

1 Ontology

Definition 1: An entity E is defined as a set of properties $\{p_1, p_2, \dots, p_n\}$.

Axiom 1: Every entity exists in a four-dimensional space-time.

Theorem 1: If an entity E interacts with another entity F , then at least one property of E or F undergoes a transformation.

$$E \xrightarrow{\text{Interaction}} E' \quad (1)$$

Definition 2: State Space and Transition A system state S_t at time t is a configuration of all observable properties. The evolution of the system is the sequence of transitions $S_0 \rightarrow S_1 \rightarrow S_2 \rightarrow \dots$ in the State Space $\mathcal{S}$.

Definition 3: Transition Probability Vector ($\mathbf{V}_t$) For a given state S_t , the set of possible transitions to the next state S_{t+1} is represented by the vector $\mathbf{V}_t = \{P_1, P_2, \dots, P_n\}$, where P_i is the probability of transitioning to the i -th accessible state, and $\sum P_i = 1$.

Axiom 2: Combinatorial Quantization of Time (Δt_{phys}) The transition between two subsequent states, $S_t \rightarrow S_{t+1}$, is not deterministic but governed by the vector $\mathbf{V}_t$. Time is quantized, and the smallest temporal unit (Δt_{phys}) is a measure of the combinatorial capacity of the transition probabilities: the more possibilities, the shorter the resulting time quantum.

$$\Delta t_{\text{phys}} \propto \frac{\mathcal{K}}{\prod_{i=1}^n P_i} \quad (2)$$

where $\mathcal{K}$ is a fundamental constant, and $\prod P_i$ is the product of all probabilities in the transition vector $\mathbf{V}_t$.

Conjecture 1.1: The Fascicle of Temporal Axes The instantaneous temporal evolution is best represented by a **Fascicle of Temporal Axes** in a projected $\mathbb{R}^3$ space, all intersecting at a single origin. Each potential transition from a state S_t is mapped onto an axis defined by its unique combination of inclination ($\theta \in [0, 2\pi]$) and angular coefficient (m), where $m = \tan(\alpha)$ for

$\alpha \in (-\pi/2, \pi/2)$. The discrete states S_n lie along these axes. The parametric equation generating the fascicle of axes $\mathcal{L}$ is:

$$\mathcal{L}(\lambda, \alpha, \theta) = \lambda \cdot \begin{pmatrix} \sin(\alpha) \cos(\theta) \\ \sin(\alpha) \sin(\theta) \\ \cos(\alpha) \end{pmatrix} \quad (3)$$

where $\alpha \in [0, \pi]$ represents the inclination from the vertical axis (e.g., $m = \tan(\alpha)$ for a specific projection), and $\theta \in [0, 2\pi]$ represents the rotation.

2 The Mathematical Object as an Agent of Action and Materialization

In this section we introduce a geometric-variational entity, called the *Simple* (Agent of Action and Materialization). A Simple is a closed, deformable surface whose behavior is entirely governed by its intrinsic geometry. No physical medium is assumed either inside or outside the surface: all “dynamics” emerge solely from the surface itself.

The Simple generates forces directly from its geometry. These forces are not imposed from outside but arise internally as variational responses to changes in area and curvature. Surface tension contributes an energetic drive toward minimizing area, while bending rigidity resists curvature deviations. Together, these geometric contributions determine the forces that act on the surface and govern its admissible deformations.

When multiple Simples are arranged in a network, additional forces arise from their geometric interactions, specifically from the formation, deformation, and dissolution of shared films. All transitions of the system are therefore determined by the interplay between (i) forces generated intrinsically by each Simple and (ii) forces generated extrinsically by local contact with neighbors. The resulting evolution is purely variational: surface shapes change only along directions that decrease the total energy under the constraints imposed.

2.1 Geometric State Space

Definition 4: Surface State Let Σ be a smooth, closed, oriented two-dimensional surface embedded in $\mathbb{R}^3$. A *state* of the Mathematical Object is a triple

$$(\Sigma, H, K)$$

where $H : \Sigma \rightarrow \mathbb{R}$ is the mean curvature field and $K : \Sigma \rightarrow \mathbb{R}$ is the Gaussian curvature field. Two states are identical if their embeddings coincide up to smooth reparameterization.

Axiom 3: Infinitesimal Locality The energetic contribution of the Object at each surface point depends only on the infinitesimal geometry in a neighborhood of that point: specifically on H , H_0 , K , and the area element dA .

This axiom ensures that the Object is fully characterized by its curvature distribution, not by global coordinates or external embedding choices.

2.2 Energy Landscape

Definition 5: Surface Energy Functional. For each state (Σ, H, K) we define the energy

$$E[\Sigma] = \int_{\Sigma} \gamma dA + \int_{\Sigma} k (H - H_0)^2 dA,$$

where $\gamma > 0$ is a surface-tension constant, $k \geq 0$ is a bending rigidity constant, and H_0 is a reference curvature field.

This functional prescribes that the Object tends to reduce surface area while also resisting deviations of curvature from H_0 .

Axiom 4: Variational Evolution. Allowed transitions between states of the Object are precisely those deformations of Σ which reduce the value of E . No transition that increases energy is permitted.

This axiom replaces any notion of physical time with a purely variational ordering of states.

2.2.1 Variational Surface Force.

Although no physical dynamics are present, the variational structure of E induces a natural notion of *force*: the directional derivative of the energy under an infinitesimal normal deformation of the surface.

Let $\phi : \Sigma \rightarrow \mathbb{R}$ be a smooth scalar field and consider the normal deformation

$$\Sigma_{\varepsilon} = \{ x + \varepsilon \phi(x) \mathbf{n}(x) : x \in \Sigma \},$$

where $\mathbf{n}$ is the unit normal. The first variation of the energy is defined by

$$\delta E[\phi] = \left. \frac{d}{d\varepsilon} \right|_{\varepsilon=0} E[\Sigma_{\varepsilon}].$$

The *force density* acting on the surface is then the functional derivative

$$\mathcal{F} = - \frac{\delta E}{\delta \Sigma},$$

characterized implicitly through

$$\delta E[\phi] = - \int_{\Sigma} \mathcal{F} \phi dA.$$

For the energy functional above, the resulting geometric force is

$$\mathcal{F} = \gamma H - 2k \Delta_{\Sigma}(H - H_0) - 2k (H - H_0) (H^2 - K),$$

where Δ_{Σ} denotes the Laplace–Beltrami operator.

This force has two contributions:

- *Surface-tension term:* γH , which drives the Object to reduce surface area.

- *Bending term:*

$$-2k \left[\Delta_{\Sigma}(H - H_0) + (H - H_0)(H^2 - K) \right],$$

which penalizes deviations of curvature from H_0 and introduces higher-order geometric smoothing effects.

A deformation is admissible precisely when it moves the surface in a direction that does not increase energy; equivalently, when

$$\int_{\Sigma} \mathcal{F} \phi dA \geq 0.$$

Thus, the force $\mathcal{F}$ determines the intrinsic geometric bias governing the allowed transitions of the Object.

2.2.2 Effect of Area Conservation on Surface Forces

In the previous formulation, the surface-tension term γH acts to locally reduce the surface area. However, the *Per-Simple Area Conservation* constraint

$$\int_{\Sigma} dA = A_0$$

modifies the admissible deformations: any local tendency to shrink or expand must be exactly compensated elsewhere on the surface.

Mathematically, this constraint is introduced via a Lagrange multiplier λ , leading to a *constrained variational force*:

$$\mathcal{F}_{\text{constrained}} = \gamma H + \lambda,$$

where λ is determined such that

$$\int_{\Sigma} \phi dA = 0$$

for any admissible normal deformation ϕ .

Interpretation 2.1:

- The surface-tension term no longer globally reduces the total area.
- Instead, it drives local *redistribution of area*, producing bumps and compensating depressions while preserving A_0 .
- When multiple simples interact, local area changes propagate to the rest of the surface to satisfy the constraint, explaining the instantaneous, nonlocal redistribution of deformations across the network.

Thus, area conservation converts the purely shrinking effect of surface tension into a mechanism for controlled redistribution of the surface, fully consistent with the variational evolution of the object.

2.3 Interaction of Multiple Objects

Let $\{\Sigma_i\}$ denote several Mathematical Objects in proximity.

Definition 6: Interaction Energy For two surfaces Σ_i and Σ_j that meet or approach one another, we define an additional interaction contribution

$$E_{\text{int}}[\Sigma_i, \Sigma_j]$$

which depends on the geometry of the shared boundary or film. The total system energy is

$$E_{\text{tot}} = \sum_i E[\Sigma_i] + \sum_{i < j} E_{\text{int}}[\Sigma_i, \Sigma_j].$$

Axiom 5: Local Geometric Interaction Changes in the geometry of Σ_i modify the interaction energy with all neighbors Σ_j through their shared curvature and area elements. Thus the energy gradient for Σ_i depends on its own curvature fields and on the curvature fields of neighboring surfaces.

This ensures path dependence and non-local branching behavior.

2.4 Transition Structure

Definition 7: Accessible States From a given state Σ_n , the set of admissible next states is

$$\mathcal{S}(\Sigma_n) = \{\Sigma_{n+1} : E_{\text{tot}}(\Sigma_{n+1}) < E_{\text{tot}}(\Sigma_n)\}.$$

Definition 8: Transition Probability Vector If the evolution is stochastic, the transition probability from Σ_n to $\Sigma_{n+1}^{(k)} \in \mathcal{S}(\Sigma_n)$ is given by

$$P(\Sigma_{n+1}^{(k)} | \Sigma_n) = \mathcal{F}\left(\frac{\delta E_{\text{tot}}}{\delta \Sigma_n}, \{\Sigma_j : \Sigma_j \text{ neighbors of } \Sigma_n\}\right),$$

where $\mathcal{F}$ is a map assigning probabilities based on the full curvature distribution of Σ_n and its neighbors.

In a deterministic formulation, the transition probability vector P associated with a given Simple Σ_n is composed of a finite set of probability values describing the possible transitions from Σ_n to the admissible states $\Sigma_{n+1}^{(k)} \in \mathcal{S}(\Sigma_n)$. The number of components of this vector depends on the number of Simples that influence the evolution of Σ_n through the global constraint of area conservation. This quantity represents the set of Simples whose geometric state contributes to the determination of the next configuration of Σ_n .

Each component P_k of the transition vector is determined by the configuration of each Simple's properties (Definition 2). The value of the k -th probability component is defined as

$$P_k = \frac{1}{z} \prod_{n=1}^z \Phi(n) x(n),$$

where z is the number of properties and $x(n)$ denotes a function of the n -th contributing property that participate in the definition of the state of Σ_n (for instance the areas or curvatures of the patches). The factor $\Phi(n)$ is a trigonometric phase term of the form

$$\Phi(n) = e^{i\theta_n},$$

where θ_n represents the phase associated with the geometric configuration of the n -th property of the current Simple. Under this formulation, each transition probability is obtained from the product of the state variables of the contributing Simple modulated by their associated phase factors, and normalized by the number of properties z .

These transition probabilities define the temporal structure of the system itself. The evolution from Σ_n to Σ_{n+1} is not governed by an external clock but emerges from the combinatorial capacity of the transition vector. Each component P_k , being a product of z phase-modulated variables, represents a coherent geometric negotiation among the contributing Simples.

If the characteristic scale L_s of a Simple corresponds to the fundamental scale of the manifold, the constant $\mathcal{K}$ introduced in Axiom 2, representing the minimal action required for a transition, can be identified with the reduced Planck constant $\hbar$. In this case, the emergent temporal measure associated with the transition is

$$t \approx \frac{\hbar}{\prod_k P_k}.$$

Here, $\hbar$ is interpreted as a geometric scaling factor linking the collective product of phase-modulated contributions to the emergence of time. Time t quantifies the system's capacity to resolve its internal state under the global constraints imposed by area conservation.

Proposition 1: Normalization In order to ensure consistency with Definition 3, the transition probabilities introduced above are constructed through a two-step process. First, each admissible transition $\Sigma_{n+1}^{(k)}$ is assigned an unnormalized weight W_k determined by the phase-modulated configuration of the properties of Σ_n . The weight associated with the k -th transition is defined as

$$W_k = \prod_{n=1}^z \Phi(n) x(n),$$

where z denotes the number of properties defining the state of the Simple, $x(n)$ is a function of the n -th property (for instance the area or curvature of a patch), and $\Phi(n)$ is the associated phase factor

$$\Phi(n) = e^{i\theta_n}.$$

Because the phase term introduces complex contributions, the weights W_k cannot be interpreted directly as probabilities. The transition probabilities are

therefore obtained through a normalization procedure applied to the magnitude of these weights. Let

$$\mathcal{Z} = \sum_k |W_k|$$

be the normalization factor over the set of admissible transitions. The transition probability associated with the k -th state is then defined as

$$P_k = \frac{|W_k|}{\mathcal{Z}}.$$

By construction, this definition satisfies the normalization condition

$$\sum_k P_k = 1,$$

thereby ensuring consistency with Definition 3. Under this formulation, the transition probability vector encodes the collective influence of the phase-modulated properties of the Simple while preserving the probabilistic interpretation required for the evolution of the system.

Proposition 2: Interpretation as a discrete path-integral structure

The phase-modulated structure of the transition weights admits an interpretation that is formally reminiscent of discrete path-integral formulations used in quantum mechanics. In the present framework, each admissible transition $\Sigma_{n+1}^{(k)}$ corresponds to a possible configuration of the properties of the Simple. The associated weight

$$W_k = \prod_{n=1}^z e^{i\theta_n} x(n)$$

can therefore be interpreted as a complex amplitude determined by the geometric configuration of the contributing properties.

In conventional path-integral formulations, the evolution of a system between two states is described as a sum over all possible trajectories, each trajectory contributing a complex amplitude whose phase depends on the associated action. Although the present model is formulated on a discrete lattice of Simples rather than on continuous trajectories, the transition structure exhibits a similar mathematical pattern: the possible evolutions of a state are represented by a set of phase-weighted amplitudes whose normalized magnitudes determine the observable transition probabilities.

Within this interpretation, the phase factors $\Phi(n) = e^{i\theta_n}$ encode the geometric contribution of the properties of the Simple in a manner analogous to phase contributions in quantum amplitudes. The normalization procedure leading to the probabilities P_k can therefore be viewed as the probabilistic projection of an underlying complex amplitude structure.

This analogy suggests that the lattice of Simples may be interpreted as a discrete geometric substrate in which the evolution of the system is governed by

interference among phase-modulated configurations. In this sense, the transition structure of the model shares formal similarities with discrete path-integral descriptions of quantum evolution.

Theorem 2: Path Dependence Let $\Sigma_n \rightarrow \Sigma_{n+1}$ be an admissible transition. Then the accessible set at the next step satisfies

$$\mathcal{S}(\Sigma_{n+1}) \neq \mathcal{S}(\Sigma_n)$$

whenever the deformation modifies the curvature field on any nonzero-measure subset of Σ_n .

Proof. Any deformation that changes the curvature distribution or the geometry of contact with neighbors alters the energy gradient, hence changes the set of energy-lowering directions. Thus the set of admissible next states is modified. $\square$

Corollary 2.1: Branching Evolution The evolution of the Mathematical Object along energy-decreasing states necessarily generates a branching structure of possible future states. Each transition selects one branch and simultaneously produces a new set of future possibilities. This corollary expresses the core feature: the Object is generative, nonlinear, and history-dependent.

Conjecture 2.1: Entropy Link

An additional insight arises from the logarithmic structure of the temporal measure

$$t \approx \frac{\hbar}{\prod_k P_k}.$$

Taking the logarithm of both sides yields

$$\ln t \approx \ln \hbar - \sum_k \ln P_k.$$

The term $\sum_k \ln P_k$ represents a logarithmic measure of the combinatorial uncertainty associated with the transition vector. Although distinct from the classical Shannon entropy $H = -\sum_k P_k \ln P_k$, it plays a related role in quantifying the informational complexity of the transition structure.

Within this interpretation, the emergent temporal measure grows with the informational richness of the admissible transitions. Time therefore reflects the combinatorial complexity that the lattice must resolve in order to realize a new configuration.

2.5 Network of Simples and Area Conservation

Definition 9: Lattice of Simples Let $\mathcal{I}$ index an infinite (or finite) cubic lattice. For each $i \in \mathcal{I}$ let $\Sigma_i \subset \mathbb{R}^3$ be a smooth, closed, oriented surface (a “simple”) with neighbor set $N(i)$ satisfying $|N(i)| = 6$.

Definition 10: Contact and Free Patches Each surface decomposes into contact and free regions,

$$\Sigma_i = \Sigma_i^- \cup \Sigma_i^+, \quad \Sigma_i^- \cap \Sigma_i^+ = \emptyset,$$

where Σ_i^- is the union of all patches shared as films with neighbors and Σ_i^+ is the exposed (void) portion.

Axiom 6: Per-Simple Area Conservation There exists a constant $A_0 > 0$ such that for every i ,

$$A_i = \int_{\Sigma_i} dA = A_0.$$

Equivalently $A_i^- + A_i^+ = A_0$, where $A_i^\pm = \int_{\Sigma_i^\pm} dA$.

Definition 11: Total Energy of the Network The network energy is

$$E_{\text{tot}} = \sum_{i \in \mathcal{I}} \int_{\Sigma_i} \left(\gamma + \frac{\kappa}{2} (2H_i)^2 \right) dA + \sum_{i < j} E_{\text{int}}(\Sigma_i, \Sigma_j),$$

with E_{int} describing geometric interaction between contacting simples.

Axiom 7: Variational Evolution with Constraints Valid transitions must decrease E_{tot} while respecting the constraints $A_i = A_0$ for all i . The constrained first variation must vanish:

$$\delta E_{\text{tot}} + \sum_i \lambda_i \delta A_i = 0$$

for appropriate multipliers $\{\lambda_i\}$.

Proposition 3: Global Redistribution under Local Change A local change of contact area on Σ_i (i.e. $\delta A_i^- \neq 0$) modifies the constrained Euler–Lagrange equations for Σ_i and for every neighbor Σ_j , $j \in N(i)$. Consequently the new admissible minimizer for E_{tot} requires geometric adjustments on Σ_i and a possibly nonlocal readjustment across a connected region of the network.

Sketch. The variational derivative of E_{tot} with respect to normal deformations of Σ_i contains terms depending on Σ_i and on the contact geometry entering $E_{\text{int}}(\Sigma_i, \Sigma_j)$. Hence δA_i^- alters the energy gradient for both Σ_i and its neighbors. The constrained minimization problem then requires solving coupled Euler–Lagrange equations (elliptic in character) on the network, producing nonlocal adjustments. $\square$

3 The Non-Markovian Nature of Reality

This section formally defines the system’s dependency on its historical path, contradicting the Markovian assumption, by grounding it in the continuous geometric rearrangement of the Agent lattice required by the Area Conservation Axiom.

Definition 12: Informational Distance The distance $d(S_a, S_b)$ between two states S_a and S_b in the State Space $\mathcal{S}$ is defined not by spacetime coordinates, but by the minimum number of consecutive interactions (**variational steps**) required to transition from S_a to S_b .

Axiom 8: Path Dependency (Non-Markovian Evolution) The transition probability from the current state S_t to the next state S_{t+1} depends not only on S_t but on the entire sequence of interactions that forms the system's history $\mathcal{H}_t = \{S_0, S_1, \dots, S_t\}$.

$$P(S_{t+1}|S_t) \neq P(S_{t+1}|S_t, \mathcal{H}_{t-1}) \quad (4)$$

Theorem 3: Constraint-Induced Retrospective Influence Due to the **Per-Simple Area Conservation** (Axiom 6), any local geometric change (interaction) on Σ_i necessitates an instantaneous, constrained redistribution of geometry across the connected network (Proposition 3). This global geometric adjustment ensures that a future interaction, $\mathcal{I}_{\text{future}}$, dynamically modifies the admissible state transitions ($P(S_{t-1} \rightarrow S_t)$) of a past interval by altering the landscape of energy minima E_{tot} , making the realized path topologically reinforced.

$$\mathcal{I}_{\text{future}} \implies \text{Global Geometric Rearrangement} \implies \uparrow P(S_{t-1} \rightarrow S_t) \quad (5)$$

Corollary 3.1: Memory as Collapse The formation of memory about a specific state transition is the local collapse of the probability function, annihilating all counterfactual branches and stabilizing the current history. This collapse corresponds to the network settling into a newly reinforced local minimum of the total variational energy E_{tot} .

4 Cosmological Boundaries and Entanglement

This section integrates the concepts of Black Holes and the Multiverse into the system's boundaries, linking the ultimate limits of the network to the principle of non-local geometric connectivity.

Axiom 9: The Black Hole as the Boundary ($\mathcal{B}$) The event horizon of a black hole is the physical manifestation of the system's boundary ($\mathcal{B}$) separating our causal universe ($\mathcal{U}$) from the external region of maximum potential (Ω_0).

Definition 13: Atavistic Entanglement ($\mathcal{E}_{\text{atavistic}}$) The interaction that sustains the black hole's boundary (Hawking Radiation) implies a fundamental, non-local connection between the state of the external region (containing all futures) and the state of our universe. This connection is maintained by an entanglement $\mathcal{E}_{\text{atavistic}}$, which is independent of the informational distance $d(S_a, S_b)$ and is geometrically enforced by the **Global Redistribution under Local Change** (Proposition 3) across the network of simples.

$$\mathcal{E}_{\text{atavistic}} \sim \mathcal{I}(\mathcal{U}, \Omega_0) \quad (6)$$

Conjecture 4.1: Cosmological Bounce (Cyclicity) The ultimate state of the universe is cyclically governed by a mechanism similar to the Big Bounce, where the expansion is reinterpreted as the **total complexity (tortuosity) of all possible informational paths**. The maximum expansion is the maximum path complexity ($d_{\max}$), which forces the system to reset through an Annihilation event, resulting in the genesis of a new universe ($\Omega_0 \rightarrow S_0$).

$$\text{Big Bounce} \iff \max(d_{\text{total}}) \quad (7)$$

Axiom 10: Redshift as Tortuosity The cosmological redshift observed in distant galaxies is a measure of the accumulated informational distance ($d_{\max}$) or tortuosity of the spacetime network between the source and the observer. The stretching of the photon's wavelength reflects the increase in the number of geometric interaction steps required across the expanding variational network.

5 Variational Geometry, LQG, and String Theory

This section proposes a formal link between the variational network of simples and the major frameworks of quantum gravity, interpreting the network's geometry as the underlying physical realization of quantum spacetime, from which both Loop Quantum Gravity (LQG) and specific aspects of String Theory derive.

5.1 The Simples as Fundamental Membranes

Interpretation 5.1: LQG, String Theory, and the Simples Lattice The lattice of fundamental Agents (Σ_i) serves as the geometric foundation for both major approaches to quantum gravity:

- **Loop Quantum Gravity (LQG):** The discrete structure of a **spin network** (the graph representing quantum geometry) is the emergent structure arising from the contact geometry of the simples (Σ_i). When neighboring simples fuse along their contact patches (Σ_i^-), the shared boundaries form the **edges** and **nodes (intertwiners)** characteristic of the quantum spacetime foam.
- **String Theory (Membranes):** The fundamental surfaces (Σ_i) themselves are identified as the **Membranes (D-branes)** of String Theory. These entities are inherently subject to vibration due to their variational properties (minimization of $E[\Sigma]$, Definition 5) and dynamic interactions with neighbors (Definition 6). Only surfaces (2-branes) that respect the area conservation constraint ($A_i = A_0$) are admissible.

The minimal area constraint ($A_i = A_0$) ensures the quantization of these geometric elements.

Observation: The evolution of both the spin network and the vibrational state of the membranes is not entirely deterministic at the level of individual transitions, but follows transition amplitudes derived from quantum constraints, represented generally by $\mathcal{A} = \langle s_{\text{final}} | \hat{H} | s_{\text{initial}} \rangle$.

Conjecture 5.1: Path Coherence and Loops The **loops** or closed paths used to define the quantum geometry in LQG correspond to topologically closed paths of simplices that maintain a coherent geometric state over time. These paths can encompass regions of the simple surface that are locally disconnected (i.e., not in contact) from the neighboring simple lattice, representing independent geometric degrees of freedom.

5.2 The Hidden Variational Mechanism

Question: If the probabilistic transitions of quantum gravity are known, what governs the actual realization of one amplitude over another in the physical world?

Axiom 11: The Variational Hidden Variable The apparent randomness of quantum transitions (including spin network evolution and membrane vibration modes) is not fundamental, but arises from ignorance about the underlying geometric optimization process. The actual realization of a transition $S_t \rightarrow S_{t+1}$ is determined by the specific path that yields the greatest reduction of the **Total Network Energy** (E_{tot}), subject to the constraints (Axiom 7). The true "hidden variable" is the specific **energy gradient** $\delta E_{\text{tot}} / \delta \Sigma$ at the moment of transition.

Philosophical Statement: The engine of reality is not governed by purely probabilistic chance, but by an **imperative of geometric minimization**. The presence of order, structure, and continuity is a direct consequence of the network's continuous effort to achieve a minimum energy state while respecting the local area conservation constraints.

6 Metrics and Topology of the Variational Space-time Network

This section formalizes the structure and measurement rules for the quantized State Space network ($\mathcal{S}_{\text{network}}$), grounding its topology in the geometric properties of the Simple lattice (Σ_i).

Definition 14: Variational Network Topology ($\mathcal{S}_{\text{network}}$) The $\mathcal{S}_{\text{network}}$ is the lattice of fundamental geometric Agents (Σ_i) where the structure and dynamics are defined by the variational energy principle.

- **Vertices (V):** Represent the quantized possible states (S_t), corresponding to specific equilibrium configurations of the Σ_i surfaces (local minima of E_{tot}).
- **Edges (E):** Represent the admissible transitions (interactions) between states, weighted by the non-Markovian transition probability $P(S_t \rightarrow$

S_{t+1}), which is derived from the energy gradient $\delta E_{\text{tot}}/\delta \Sigma$ (**Definition 8**).

Theorem 4: Informational Geodesic The transition between two states S_a and S_b follows an informational geodesic $d(S_a, S_b)$. This distance is the minimum or maximum accumulated change in total network energy required for the transition (minimum/maximum number of geometric interactions):

- d_{min} (Shortest Path): Corresponds to the most efficient energy-lowering path ($\min \Delta E_{\text{tot}}$), characterizing habitual or deterministic behavior (low entropy/Sterile Cycle).
- d_{max} (Longest Path): Corresponds to the least efficient path (high accumulated geometric interaction), characterizing emergent choice, complexity, and high cognitive effort (high entropy).

Definition 15: Topological Cyclicity (Non-Linear Time) The State Space network permits **Topological Cyclicity**, meaning the system can transition from a state S_a to a subsequent state S_b and later return to a state S'_a that is geometrically equivalent to S_a , even though the path of transitions taken is entirely novel: $S_b \rightarrow S_c \rightarrow \dots \rightarrow S'_a$. This non-linear evolution is a consequence of the constant global geometric rearrangement required by the Per-Simple Area Conservation (Axiom 6), ensuring that the underlying **history** ($\mathcal{H}_t$) is unique for every realization.

Axiom 12: Interaction as Temporal Unit An instant of time is defined only by a geometric **Interaction** ($\mathcal{I}$), corresponding to an admissible deformation of the Simple surface ($\delta E_{\text{tot}} \neq 0$). The temporal distance between two instants is zero if the number of unique interactions is zero. The network is thus inherently dynamic, and Δt_Q is the time required for a singular, coherent, system-level Directive Action.

7 Agglomerates, Swarm, and the Emergence of Geometry

This section formalizes the hierarchical structure of matter, from the fundamental geometric Simple to the emergence of conscious entities, and their role in perturbing the network's stability.

Definition 16: Elementary Particle Configuration ($\mathcal{P}$) An Elementary Particle is not a point-like entity, but a stable, localized, and highly coherent geometric configuration ($\mathcal{P}$) within the lattice of fundamental Agents (Σ_i). This configuration is sustained by continuous, minimal-energy transitions (E_{tot}).

Axiom 13: Propagation as Wave Configuration The movement of an elementary particle, such as a photon, is the propagation of its specific geometric configuration ($\mathcal{P}$) as a wave of minimal energy deformation across the network of Agents (Σ_i). The maximum speed (c) corresponds to the most efficient energy-lowering path through the lattice.

Definition 17: Agglomerate An Agglomerate ($\mathcal{A}$) is a macroscopic structure (physical or informational) characterized by a high local density of coherent, synchronized states. Agglomerates manifest the collapse of probabilistic potential over time.

Axiom 14: Swarm Dynamics The collective behavior of all entities, from particles to complex structures (**the Swarm**, $\mathcal{S}_{\text{warm}}$), adheres to the Law of Large Numbers (LGN). As the number of interactions increases, the average of individual choices ($\mathcal{I}$) converges towards the maximum expected transition probability ($\max P_{\text{transition}}$).

$$\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{i=1}^N \mathcal{I}_i \rightarrow \text{Expected Value} \quad (8)$$

Conjecture 7.1: High Probability Accumulation The regions of the State Space occupied by Agglomerates (e.g., historical facts, societal conventions) become **Accumulations of High Probability** ($P \approx 1$), representing the lowest informational distance (d_{min}) and the highest degree of predictability within the system.

Definition 18: The Sterile Cycle

The Sterile Cycle (C_{sterile}) is the regime where the system evolves strictly along paths of minimum informational distance (d_{min}). It is characterized by maximum order, maximum predictability, and the absence of conscious perturbation, leading to a closed loop where the final state returns probabilistically to the initial state.

Axiom 15: Creative Capacity and Directive Action

Creative Capacity is the ability of a conscious entity (**Being**), an Agglomerate reaching the Δt_Q coherence, to generate novel geometry within the $\mathcal{S}_{\text{network}}$. This action (**Directive Action**) is achieved not by generating new energy, but by actively imposing informational limits on the total potential of the Fertile Null-State (Ω_0), thereby restricting the phase space of subsequent interactions.

Theorem 5: Disequilibrium and Network Complexity

The co-existence of multiple evolving Agglomerates with differing Directive Actions creates a state of **Disequilibrium**. This imbalance increases the total network complexity ($\uparrow d_{\text{max}}$) and unpredictability, as the evolution of any single Agglomerate ($\mathcal{A}_1$) is modified by the probabilistic feedback ($\mathcal{F}$) of all other Agglomerates ($\mathcal{A}_n$), thereby perturbing the Sterile Cycle.

$$\mathcal{A}'_1 = \mathcal{A}_1 + \sum_{n=2} \mathcal{F}(\mathcal{A}_n, \Delta t_Q) \quad (9)$$

Corollary 5.1: The Necessity of Being The existence of conscious entities is necessary to prevent the system's collapse into the Sterile Cycle, as their Directive Action constantly injects new geometry and maintains the informational distance (d_{max}) required for high complexity and the ongoing evolution of reality.

8 The Null-State and Causal Gradient Reversal

This section formalizes the concept of the "Fertile Null-State" as the state of maximum potential and the mechanism for reversing the causal probability gradient.

Definition 4: The Fertile Null-State (Ω_0) The Fertile Null-State (Ω_0) is a state of maximum potential where all possible outcomes coexist in superposition (analogue to the quantum vacuum). It is a state of zero informational entropy, but maximum energy density.

Axiom 4: Annihilation and Causal Gradient Reversal The transition between two defined Null-States ($\Omega_1 \rightarrow \Omega_2$) requires an Annihilation event, which is the singular point of the system's history. This transition forces a reversal in the **gradient of probabilistic causality**, allowing informational feedback loops to dominate the subsequent path selection.

Conjecture 8.1: Geometric Singularity Avoidance Due to the system's inherent geometric quantization (Δt_{phys} defined by the Σ_i transitions), the Annihilation event does not result in a singularity ($t = 0$). Instead, the gradient reversal triggers a topological rearrangement across the entire network (Global Redistribution, Proposition 3), which maintains the continuity of the informational network by enforcing the non-linear, cyclical possibility of returning to geometrically equivalent states via novel paths.

Theorem 6: The Longest Path The passage through the Annihilation event and the subsequent reversal forces the system to evolve along the **Longest Informational Distance** (d_{max}), defined as the path requiring the maximum number of consecutive interactions, maximizing the accumulated time (entropy) and complexity of the new reality.

9 Hierarchy of Temporal Quanta

This section defines the multi-level structure of time, linking the constraints of fundamental physics to emergent cognitive phenomena, and establishing the formal unit of consciousness (Δt_Q).

Definition 20: Planck Time (t_P) The smallest meaningful temporal unit in known physics, defined by the fundamental constants $\hbar$, G , and c . This represents the ultimate resolution of the physical universe, or the base frequency of the Ω_0 state.

$$t_P = \sqrt{\frac{\hbar G}{c^5}} \approx 5.39 \times 10^{-44} \text{ s} \quad (10)$$

Definition 21: Fluctuation Quantum (Δt_E) The maximum duration for which a given energy ΔE can be 'borrowed' from the vacuum, sustaining the existence of virtual particles (Heisenberg's Indeterminacy Principle).

$$\Delta t_E \leq \frac{\hbar}{2 \cdot \Delta E} \quad (11)$$

Theorem 7: Emergence of the Fundamental Cognitive Quantum (Δt_Q) The Fundamental Cognitive Quantum (Δt_Q) emerges when a multitude of Δt_E fluctuations organize into a stable **Domain of Coherence** (DC). This organization corresponds to a specific electromagnetic frequency (ω_C) associated with high-order cognitive processes (e.g., $F \approx 22.6$ Hz). This coherence is the minimum duration required for the **Directive Action** (Axiom 15) to be initiated by a **Being**.

$$\Delta t_Q = \frac{1}{\omega_C} \quad (12)$$

Corollary 7.1: The Macro-Micro Ratio The Cognitive Quantum is an emergent, macroscopic phenomenon, related to the fundamental scale by an immense scaling factor ($\mathcal{R}$):

$$\mathcal{R} = \frac{\Delta t_Q}{t_P} \approx 8.2 \times 10^{42} \quad (13)$$

10 Directive Action, Energy, and Cognitive Cost

This section formalizes the cost associated with the conscious perturbation of the variational network, linking the emergent Cognitive Quantum (Δt_Q) to the geometric energy landscape (E_{tot}).

Definition 22: Directive Action ($\mathcal{I}_{\text{Directive}}$) A Directive Action is the non-variational perturbation of the $\mathcal{S}_{\text{network}}$ executed by a **Being** (Axiom 15) that locally restricts the set of Accessible States $\mathcal{S}(\Sigma_n)$ by imposing informational limits on the transition probabilities, thereby steering the evolution towards a path of higher informational distance (d_{max}).

Axiom 17: Energy Cost of Directive Action The execution of a Directive Action ($\mathcal{I}_{\text{Directive}}$) requires an energy input, or a diversion of variational energy, quantified by the **Cognitive Energy Cost** (ΔE_Q). This cost is proportional to the difference between the actual energy gradient of the chosen path (∇E_{actual}) and the natural, most efficient energy-lowering gradient of the Sterile Cycle ($\nabla E_{\text{sterile}}$).

$$\Delta E_Q \propto \|\nabla E_{\text{actual}} - \nabla E_{\text{sterile}}\| \quad (14)$$

The action is successful if the energy expended perturbs the geometry enough to enforce the new transition $P(S_t \rightarrow S_{t+1}) > P_{\text{max}}(\text{Sterile Cycle})$.

Theorem 8: Quantum Constraint on Action Duration A successful Directive Action requires a minimum coherent duration equal to the Fundamental Cognitive Quantum (Δt_Q):

$$\mathcal{I}_{\text{Directive}} \text{ is valid } \iff \text{Duration} \geq \Delta t_Q \quad (15)$$

The Cognitive Quantum thus represents the minimum time required for the Agglomerate's coherence domain to accumulate sufficient ΔE_Q to locally overcome

the Swarm Dynamics (Axiom 14) and enforce a transition away from the Sterile Cycle (Definition 18).

Conjecture 10.1: Δt_Q as the Limit of Geometric Influence The minimum time Δt_Q is the time required for the Being to impose a stable geometric perturbation that propagates across the variational network before being locally washed out by the ongoing global energy minimization (Variational Evolution, Axiom 7).

Corollary 8.1: Action and Entropy Generation Since the Directive Action enforces a path of higher informational distance ($d_{\max}$, Theorem 6), it necessarily generates complexity and informational entropy ($\uparrow d_{\max}$) in the network. This entropy generation is the non-local, permanent contribution of the Being to the total network geometry.
